ABSTRACT

Context. The Gaia-ESO Public Spectroscopic Survey using FLAMES at the VLT has obtained high-resolution UVES spectra for a large number of giant stars, allowing a determination of the abundances of the key chemical elements carbon and nitrogen at their surface. The surface abundances of these chemical species are well-known to change in stars during their evolution on the red giant branch after the first dredge-up episode, as a result of extra-mixing phenomena.

Aims. We investigate the effects of thermohaline mixing on C and N abundances using the first comparison between the Gaia-ESO survey [C/N] determinations with simulations of the observed fields using a model of stellar population synthesis.

Methods. We explore the effects of thermohaline mixing on the chemical properties of giants through stellar evolutionary models computed with the stellar evolution code STAREVOL. We include these stellar evolution models in the Besançon Galaxy model to simulate the [C/N] distributions determined from the UVES spectra of the Gaia-ESO survey and compare them with the observations.

Results. Theoretical predictions including the effect of thermohaline mixing are in good agreement with the observations. However, the field stars in the Gaia-ESO survey with C and N-abundance measurements have a metallicity close to solar, where the efficiency of thermohaline mixing is not very large. The C and N abundances derived by the Gaia-ESO survey in open and globular clusters clearly show the impact of thermohaline mixing at low-metallicity, allowing to explain the [C/N] ratio observed in lower-mass and older giant stars. Using independent observations of carbon isotopic ratio in clump field stars and open clusters, we also confirm that thermohaline mixing should be taken into account to explain the behavior of $^{12}\text{C}/^{13}\text{C}$ ratio as a function of stellar age.

Conclusions. Overall the current model including thermohaline mixing is able to reproduce very well the C- and N- abundances over the whole metallicity range investigated by the Gaia-ESO survey data.

1. Introduction

Over the last decade, the understanding of our Galaxy has dramatically increased thanks to the development of large spectroscopic surveys that provide fundamental properties of a large number of stars in different regions of our Galaxy (e.g. RAVE (Steinmetz et al. 2006), SEGUE (Yanny et al. 2009), Gaia-ESO (Gilmore et al. 2012), APOGEE (Blanton et al. 2017), LAMOST (Cui et al. 2012), GALAH (De Silva et al. 2015)). Some of them provide abundances deduced from high resolution spectra, allowing the determination of light chemical elements, such as carbon, nitrogen, or lithium.

The carbon and nitrogen abundances and also the carbon isotopic ratio are key chemical tracers to constrain the stellar evolution of giant stars. Indeed, low-mass stars experience the well-known first dredge-up at the bottom of the red giant branch, implying changes of the surface abundances of C and N (Iben 1967). After this episode, numerous spectroscopic observations show that an extra-mixing occurs after the bump luminosity on the red giant branch changing the abundances of elements lighter than oxygen at the surface of bright red-giant stars (e.g. Gilroy 1989; Gilroy & Brown 1991; Gratton et al. 2000; Luck 1994; Tautvaišienė et al. 2000; Tautvaišienė et al. 2001, 2005; Smiljanic et al. 2009; Mikolaitis et al. 2010, 2012).

Different transport processes have been discussed in the literature to explain the abundance anomalies in giants. Parametric computations have been proposed to better understand the behaviour of chemical abundances at the stellar surface in low- and intermediate-mass stars. After showing that the Hot Bottom Burning (HBB) process, which was previously proposed by Cameron & Fowler (1971) to allow Li production in AGB stars, can explain the oxygen isotopic ratios in AGB stars with initial stellar mass between 4.5 and 7.0 M, Boothroyd et al. (1995) introduced the notion of Cool Bottom Processing (i.e., ad hoc transport material from the cool bottom of stellar convective envelope to deeper and hotter radiative regions where nuclear reactions occur), to explain surface abundances of giant stars with masses lower than 2.0 M_⊙ (see also Wasserburg et al. 1995; Boothroyd & Sackmann 1999; Sackmann & Boothroyd 1999). Denissenkov & Weiss (1996) suggested like Wasserburg et al. (1995) the presence of non-standard mixing of unknown physical origin, between the hydrogen burning and the base of convective envelope after the bump to explain abundances anomalies in red giant stars. To understand variations of surface abundances of giant stars, they proposed a deep diffusive mixing (e.g. Denissenkov & Weiss 1996; Weiss et al. 1996; Denissenkov et al. 1998). Nevertheless, these two propositions of extra-mixing are then not related to any physical mechanism to explain changes in surface abundances, and depend on free parameters. On the other hand, rotation has been investigated as a possible source of mixing in RGB stars by several authors (Sweigart & Mengel 1979; Charbonnel 1995; Denissenkov & Tout 2000; Palacios et al. 2006; Chanamé et al. 2005), showing that the total transport coefficient of rotation at this phase is too low to imply abundance variation on the first ascent giant branch as requested by observations of RGB stars brighter than the RGB-bump.

Thermohaline instability driven by ³He-burning through the pp-chain has been proposed to govern the photospheric compositions of bright low-mass red giant stars (e.g. Charbonnel & Zahn 2007; Charbonnel & Lagarde 2010). This double diffusive instability, induced by a mean molecular weight inversion due to the ³He(³He,2p)⁴He reaction in the

thin radiative layer between the convective envelope and the hydrogen-burning shell (Eggleton et al. 2008; Lattanzio et al. 2015), is a physical mechanism that best reproduces the observational abundances (e.g. C, N) in giant stars (e.g. Charbonnel & Lagarde 2010; Angelou et al. 2011, 2012; Henkel et al. 2017). Few recent papers suggested that magnetic fields might play a role in stellar mixing, alone Busso et al. (2007), or in combination with thermohaline mixing (Denissenkov & Merryfield 2011; Palmerini et al. 2011). Since thermohaline provides also a physical solution of the ³He-problem well-known in the Galactic chemical evolution models (Lagarde et al. 2011, 2012), we will focus on this mechanism in this paper.

To exploit all potential of spectroscopic data, Lagarde et al. (2017) (hereafter L17) improved the Besançon Galaxy model (hereafter BGM) including the stellar evolution models that provide surface chemical and seismic properties of stars during their life. In addition to global properties, the BGM is now able to explore the effects of extra-mixing on the surface abundances of different chemical species. The BGM allows us to compute the stellar component of our Galaxy taking into account errors and the selection function of the observations, developing a consistent picture of the Galaxy with the formation and evolution scenarios of the Milky Way, stellar formation and evolution theory, models of stellar atmospheres and dynamical constraints (Robin et al. 2003; Czekaj et al. 2014). This population synthesis model is a powerful tool to improve current stellar evolution models as well as on the physics of different transport processes comparing with observations of field stars at different stellar masses, metallicities, ages, evolutionary stages, or at different locations in the Galaxy.

In this paper, we proposed to study the effects of thermohaline mixing with metallicity and mass of giant stars, using the C- and N- abundances derived for the giants in the Gaia-ESO survey. To this aim, we perform simulations using the BGM with and without the effects of thermohaline instability. Simulations and data used for this study are described in Sect.2, while the theoretical effects of thermohaline instability with stellar mass and metallicity are discussed in Sect.3. We start with field stars observed with UVES in Sect.4, and then enlarge our study to the open and globular clusters well observed by the Gaia-ESO survey and compile from literature (see Sect.4.2). We draw our conclusions in Sect.5.

2. Data set and simulations

The Gaia-ESO survey (Gilmore et al. 2012; Randich et al. 2013, hereafter GES) uses the FLAMES (Fiber Large Array Multi-Element Spectrograph) multi-fiber facility (Pasquini et al. 2002) of the VLT (Very Large Telescope) to obtain a better understanding of the kinematic and chemical evolution of our Galaxy. Giraffe the medium-resolution spectrograph (R~20 000), and UVES (Dekker et al. 2000) the high-resolution spectrograph (R~47 000) are used to observe up to 10⁵ stars in the Milky Way.

For our study, we use the observations of giant stars made with UVES, and the carbon and nitrogen abundances derived from their spectra. These giant stars lie in different Galactic regions (see Fig. 1). All data used in this paper are included in the second, fourth, and fifth internal GES data releases (iDR2, iDR4, and iDR5) to have a sample as large as possible. The main atmospheric parameters of the stars were determined as described by Smiljanic et al. (2014), the carbon and nitrogen abundances were

Fig. 1. All-sky view centered on the Milky Way Plane in an airtoff projection from Mellinger (2009) with a Galactic coordinate grid. Giants observed by the Gaia-ESO survey for which C and N-abundances are determined are identified by different colors: clusters members (red) and field stars (yellow). We also represent 9 open clusters (Collinder 261, Melotte 66, NGC6253, NGC3960, NGC2324, NGC2477, NGC2506, IC4651, NGC6134) for which $^{12}\text{C}/^{13}\text{C}$ is derived (cyan diamond, see Sect.4.3).

Fig. 2. Color-magnitude diagram for stars observed by GES survey (grey dots), and for which C and N abundances are determined (magenta dots). The color and magnitude are from 2MASS catalog.

determined as described by Tautvaišienė et al. (2015). We separated the stars into two groups:

- 324 giant field stars with 173 stars located in the Galactic bulge;
- Giants belonging to open and globular clusters (see Table 1)

The simulations were made using the revised version of BGM (Paper I of this series, Lagarde et al. 2017), where a new grid of stellar evolution models computed with the code STAREVOL (e.g. Lagarde et al. (2012); Amard et al. (2016)) has been implemented. This new grid provides the global properties (e.g. surface gravity, effective temperature) and chemical abundances (for 54 stable and unstable species). These models

take also into account the effects of thermohaline instability during the red giant branch (hereafter RGB, e.g. Charbonnel & Lagarde 2010). As discussed in Paper I, thermohaline instability changes the photospheric composition of low-mass brighter giant stars, with a decrease of carbon and an increase of nitrogen. In addition to the simulations discussed in Lagarde et al. (2017), improvements have been extended to all populations other than the thin disc, implying the computation of stellar evolution models with different α -enhancements ($[\alpha/\text{Fe}] = 0.15$ and 0.30), following the observational $[\alpha/\text{Fe}]$ vs $[\text{Fe}/\text{H}]$ trend observed by the data release 12 of APOGEE (Majewski et al. 2015). Namely, for $[\text{Fe}/\text{H}] < 0.1$:

$$[\alpha/\text{Fe}] = \begin{cases} 0.014 + 0.0140675 \times [\text{Fe}/\text{H}] + 0.101262 \times [\text{Fe}/\text{H}]^2 & \text{for the thin disc stars,} \\ 0.320 - \exp(1.19375 \times [\text{Fe}/\text{H}] - 1.6) & \text{for the thick disc stars,} \\ 0.3 & \text{for halo stars.} \end{cases} \quad (1)$$

For $[\text{Fe}/\text{H}] > 0.1$, $[\alpha/\text{Fe}]$ is assumed solar. To these relations an intrinsic Gaussian dispersion of 0.02 dex is added.

As discussed in Czekaj et al. (2014), the BGM also simulates the Poisson noise in the Monte Carlo generation of the simulated stars. We performed simulations in every GES field referred in the iDR5 using this new version of the BGM. As shown by Figure 2, all stars in the sample have $0.5 < J - K < 1.0$, and $5.0 < J < 14$ so we restricted our simulations to this color and magnitude ranges. We did two sets of simulations with and without the effects of thermohaline instability. The selection bias introduced by the additional requirement of measurable carbon and nitrogen abundances cannot be taken into account in our sample. That is why simulations produce more stars than in the sample. However this difference does not affect the conclusions of this paper.

Fig. 3. [C/N] distributions, normalised to the histogram area, of the synthetic population simulated with the BGM with (blue solid histograms) and without (grey shaded histograms) the effects of thermohaline instability during the red giant branch. Giant stars are divided into three groups: low-RGB stars (before the RGB-bump luminosity, top panel); up-RGB stars (after the RGB-bump luminosity, middle panel); and clump/early-AGB stars (bottom panel).

3. Thermohaline mixing effects on [C/N] ratio

3.1. Physics

Thermohaline mixing, as discussed in Paper I, is a double diffusive process conducted in RGB stars by an inversion of mean molecular weight induced by ${}^3\text{He}({}^3\text{He}, 2p){}^4\text{He}$ reaction (Charbonnel & Zahn 2007; Siess 2009; Charbonnel & Lagarde 2010; Henkel et al. 2017) and a temperature gradient. For this study, we use the prescriptions advocated by Charbonnel & Zahn (2007) given by Ulrich (1972) with an aspect ratio of instability fingers $\alpha \sim 6$ as referred by Krishnamurti (2003). The thermohaline diffusion coefficient used in stellar evolution models includes the correction for non-perfect gas and is given by:

$$D_t = C_t K \left(\frac{\varphi}{\delta} \right) \frac{-\nabla_\mu}{(\nabla_{\text{ad}} - \nabla)} \quad \text{for } \nabla_\mu < 0, \quad (2)$$

where K is the thermal diffusivity; $\varphi = (\partial \ln \rho / \partial \ln \mu)_{P,T}$; $\delta = -(\partial \ln \rho / \partial \ln \nu)_{P,\mu}$; $\nabla = (\partial \ln T / \partial \ln P)$, ∇_μ and ∇_{ad} being respec-

tively the molecular weight gradient and the adiabatic gradient; and with the non-dimensional coefficient

$$C_t = \frac{8}{3} \pi^2 \alpha^2. \quad (3)$$

The value of α is still discussed in the literature by hydrodynamic simulations in 2D or 3D (Denissenkov et al. 2009; Denissenkov 2010; Denissenkov & Merryfield 2011; Rosenblum et al. 2011; Traxler et al. 2011; Brown et al. 2013; Garaud & Brummell 2015). Although these simulations are still far from stellar conditions and do not take into account the coupling of this instability with other hydrodynamic processes occurring in red-giant stars (e.g. rotation, magnetic field), they predict that thermohaline instability is not efficient enough to explain surface chemical abundances (Wachlin et al. 2014) with the thermohaline fingers becoming more like blobs. Future hydrodynamical simulations closer to the conditions met in stellar interiors (Prat et al. 2015) or including the effects of other hydrodynamical processes as recently by Sengupta & Garaud (2018) would shed light on this discrepancy. Hence, we choose to use the prescriptions described above to confront theoretical predictions with current observations at different masses and metallicities.

3.2. Impact along the evolution

This double diffusive instability develops starting from the luminosity of the bump during the RGB (e.g. Charbonnel & Lagarde 2010, and Paper I). Indeed, the steady increase of the stellar luminosity along the RGB momentarily stops when the hydrogen burning shell (hereafter HBS) crosses the molecular weight barrier left behind by the first dredge-up. At that moment, indeed, the mean molecular weight of the HBS becomes smaller, which implies a decrease of the total stellar luminosity. This is the so-called bump in the luminosity function. When the region of nuclear energy production has passed this discontinuity, the mean molecular weight slightly increases and the stellar luminosity increases again. This variation of the luminosity causes an accumulation of stars in the color-magnitude diagram leading a bump in the luminosity distribution (e.g. Iben 1967, 1968; Fusi Pecci et al. 1990; Charbonnel 1994; Christensen-Dalsgaard 2015). The impact of thermohaline instability on the theoretical [C/N]¹ ratio distributions at different evolutionary states are shown in Fig.3. With stellar models, giant stars are divided into three groups: (1) low-RGB stars: stars ascending the red giant branch before the RGB bump². These stars have not yet undergone thermohaline mixing; (2) up-RGB: brighter RGB stars than the RGB-bump (with $\log g \leq 2.2$); (3) clump stars selected according to their asymptotic period spacing of g-modes $\Delta \Pi_{\ell=1}$. As discussed by Charbonnel & Lagarde (2010) and Paper I, thermohaline instability occurring at the RGB-bump luminosity changes the surface abundances of C- and N- for giant stars brighter than the RGB-bump and along the red giant branch, resulting in a decrease of [C/N] ratio (see middle panel of Fig.3). While thermohaline mixing is no longer happening in red clump stars, they have the lowest [C/N] (as

¹ $[X/Y] = A(X) - A(X)_\odot - A(Y) + A(Y)_\odot$, with $A(X) = \log(N(X)/N(H)) + 12$

² Since the gravity (and so luminosity) of the RGB-bump changes with the metallicity of stars, we establish a simple empirical relation based on stellar evolution models (without the effects of rotation on the evolutionary path) allowing the distinction of low-RGB and up-RGB stars: $\log g_{\text{RGB bump}} = 0.32 \cdot [\text{Fe}/\text{H}] + 2.44$

Fig. 4. $[C/N]$ distributions for two stellar masses ranges $0.95 \leq M/M_{\odot} \leq 1.05$ and $1.95 \leq M/M_{\odot} \leq 2.05$ (top and bottom panel, respectively) for clump stars simulated with the BGM including (blue solid histograms) or not (grey shaded histograms) the effects of thermohaline instability. The bottom panel presents the mass distributions for clump stars simulated with the BGM at both mass ranges.

shown in Fig.3) because they have undergone a full RGB phase of extra mixing.

3.3. Impact as a function of stellar mass

As discussed and explained by Charbonnel & Lagarde (2010) (see §3.1.2), the global efficiency of thermohaline mixing increases when one considers less massive stars at a given metallicity, or more metal-poor stars at a given stellar mass. This results from the combination of several factors like the thermohaline diffusion timescale compared to the secular timescale, the compactness of the hydrogen burning shell and of the thermohaline unstable region, and the amount of ^3He available to power the thermohaline instability.

Figure 4 compares the effect of thermohaline mixing on the surface abundances of red clump stars with (blue) and without (grey) extra mixing, for $1 M_{\odot}$ (upper panel) and $2 M_{\odot}$ (lower panel). On the main sequence low-mass stars (LMS, $M \lesssim 1.7 M_{\odot}$) burn hydrogen mainly through the pp-chains rather than CNO

cycle as in intermediate-mass (IMS, $1.7 \lesssim M \lesssim 2.2 M_{\odot}$). Consequently, a large production of ^3He occurs in LMS, favoring the development of thermohaline instability during the red giant branch. Then the impact on $[C/N]$ distribution is larger for $1.0 M_{\odot}$ stars than for $2.0 M_{\odot}$ stars.

On the other hand, the RGB-bump occurs on the evolution of low- and intermediate-mass stars only, and depends on the metallicity of these stars. More massive stars (HMS, $M \gtrsim 2.2 M_{\odot}$) ignite central helium-burning in a non-degenerate core at relatively low luminosity on the RGB, well before the hydrogen burning shell reaches the mean molecular weight discontinuity caused by the first dredge-up. Consequently, these objects do not go through the bump on their short ascent of the RGB, and thus thermohaline instability does not develop in this kind of star.

3.4. Impact as a function of metallicity

In low-mass, low-metallicity giants the thermohaline unstable region is more compact and has a steeper temperature gradient, resulting in a higher diffusion coefficient and then a more efficient transport process (see Fig.6 of Lagarde et al. 2011).

The effect of thermohaline mixing at two metallicities on the $[C/N]$ ratio at the surface of clump stars simulated by the BGM is shown on Fig. 5 (top and middle panels). The mass distributions for each metallicity range are also shown in Fig. 5 (bottom panel). Although thermohaline mixing has a larger impact on $[C/N]$ when the metallicity decreases, the figure clearly shows a non negligible impact at solar metallicity also.

Because of their large mass- and metallicity-ranges, field stars are key data to constrain the efficiency of thermohaline instability occurring in giant stars. In the next section, we propose to study the effects of thermohaline instability with mass and metallicity, comparing the population synthesis and the GES observations.

4. Comparison of observed and simulated chemical properties

4.1. C and N abundances in field stars

Figure 6 displays the surface $[C/N]$ ratio of giant stars simulated with the BGM (grey dots) as a function of stellar metallicity, including or not the effects of thermohaline mixing (right and left panel, respectively). Low-giants, up-RGB, and clump stars are included in this figure (as described above). This figure clearly shows a stronger impact of thermohaline instability on the surface abundances (here, $[C/N]$ ratio) of giants with $[Fe/H] < -0.5$. Lower-metallicity populations are composed essentially of low-mass stars, implying thick disc and halo as key populations to test the efficiency of this extra-mixing (see Figs. 5 and 6).

In the same figure, the $[C/N]$ ratio derived from the observed field stars are also shown (red dots). Since UVES is centred on Solar neighbourhood MSTO stars (plus bulge, see Fig.1), where about solar metallicity is expected, the metallicity range of observations is around the solar metallicity (Stonkutė et al. (2016), $-0.5 \lesssim [Fe/H] \lesssim 0.5$). Figure7 presents a comparison between the $[C/N]$ distribution predicted by the BGM including or not the effects of thermohaline instability and the observed distribution of $[C/N]$ in the GES field stars sample. Since the $[C/N]$ range in the simulation including the effects of thermohaline instability or

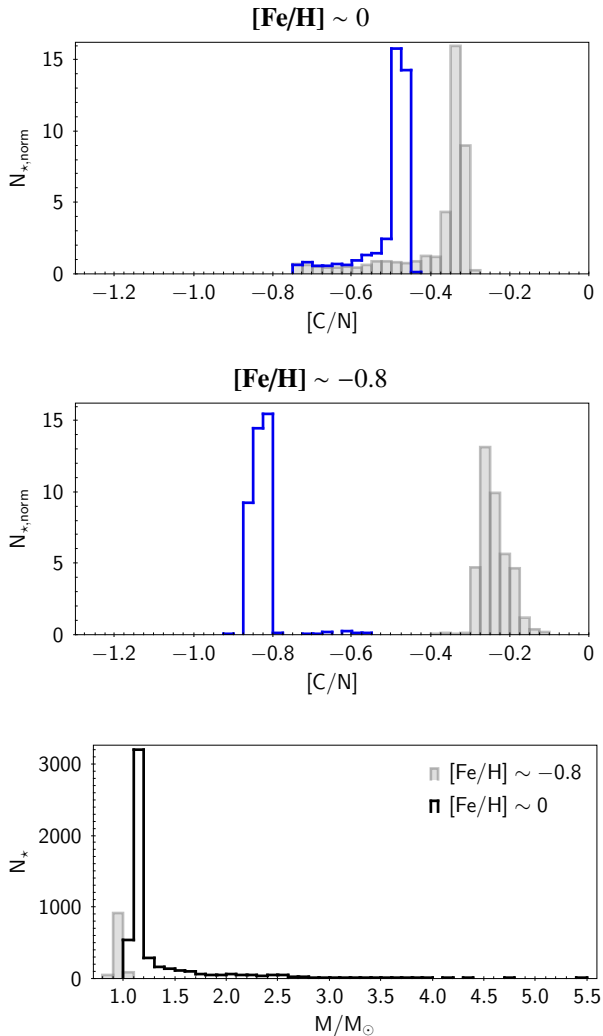

Fig. 5. $[C/N]$ distributions at two metallicities (top and middle panel, respectively) for clump stars simulated with the BGM including (blue solid histograms) or not (grey shaded histograms) the effects of thermohaline instability. The bottom panel presents the mass distributions for clump stars simulated with the BGM at $-0.85 \leq [Fe/H] \leq -0.75$ and $-0.05 \leq [Fe/H] \leq 0.05$.

following the standard theory are the same, Fig. 6 does not allow us to discriminate between both prescriptions directly. However, Fig 7 allowing a quantitative comparison, shows the necessity of extra-mixing to reproduce the observations even at higher metallicities. In this case, information on stellar masses and evolutionary states of field stars are required to add more constraints on the efficiency of extra-mixing with stellar mass. This is now possible with asteroseismology which can be combined with astrometry from Gaia (Gaia Collaboration et al. 2016), and will be discussed in a forthcoming paper.

In addition, the right panel of Fig.7 shows the simulation did specifically for NGC104 (with and without extramixing), focussing on cluster region in the sky and the specific metallicity range. The mean $[C/N]$ ratio and the standard deviation predicted by the simulations including extra-mixing ($\langle [C/N] \rangle = -0.48 \pm 0.19$) are in better agreement with observations in NGC104 ($\langle [C/N] \rangle = -0.53 \pm 0.20$), than simulation following the standard stellar evolution model ($\langle [C/N] \rangle = -0.28 \pm 0.05$). With this very promising results, we will focus on clusters observed by GES survey in the next section.

4.2. C and N abundances in clusters

GES has observed a lot of different clusters in different regions of our Galaxy (see red circles in Fig. 1), providing the homogeneous observational data needed to constrain stellar and Galactic evolutions. We investigate the $[C/N]$ ratio derived in giant members of those open and globular clusters. We do not want to study each cluster in detail, but clusters are used here as tracers of extra-mixing. Since stars belonging to a cluster were formed together, we can assume that they have the same age, distance, and metallicity; resulting in stronger constraints of thermohaline efficiency.

Figures 8, 9 and 10 show the $[C/N]$ ratio derived by GES for evolved stars belonging to different globular and open clusters as a function of metallicity, turn-off mass, and age. We also add clusters for which $[C/N]$ and $^{12}C/^{13}C$ determinations are available from the literature (not from GES): Collinder 261, Melotte 66, NGC 6253, NGC3960, NGC2324, NGC 2477, NGC 2506, IC 4651, NGC 6134 (Mikolaitis et al. 2012; Drazdauskas et al. 2016; Tautvaišienė et al. 2016; Mikolaitis et al. 2011b,a, 2010). These clusters were acquired by two complementary programmes, and were analyzed in a homogeneous way by the same group that produces C and N determinations in GES, resulting a robust comparison with our models. Individual stars are attributed the turn-off mass and age (e.g. VandenBerg et al. (2013), Chantreau’s private communication using stellar models discussed in Charbonnel & Chantreau (2016), and Drazdauskas et al in prep.) of their host clusters. Synthetic populations including or not the effects of thermohaline instability are shown (right and left panels, respectively) for low-RGB, up-RGB and clump stars (as defined in Sect.4). Simulations and observations in each cluster are a mix of giant stars at different evolutionary states (i.e. at different luminosities/gravities on the RGB), implying a large $[C/N]$ -range for the synthetic populations as well as for the determination in each cluster.

As discussed by Charbonnel & Lagarde (2010) and described in Sect.3, three mass-ranges can be evoked to quantify the efficiency of thermohaline instability.

- For low-mass and low-metallicity stars, thermohaline instability is the most efficient transport process that can change the C and N surface abundances. That’s why simulations presented here, taking into account thermohaline mixing only, reproduce very well observed $[C/N]$ in this mass range (see Fig.9) including a very good fit for stars with stellar ages higher than ~ 1 Gyr (see Fig.10).
- For intermediate-mass stars ($1.7 \leq M \leq 2.2 M_\odot$), our simulations present a slightly higher $[C/N]$ ratio than observations (see right panel of Fig.9). Charbonnel & Lagarde (2010) show that in addition to thermohaline mixing, rotation-induced mixing plays an equivalent role to change the surface abundances of these mass-range stars, resulting in a slightly lower $[C/N]$ ratio at the surface of intermediate-mass stars (see Fig.17 of Charbonnel & Lagarde (2010)).
- For high-mass stars, thermohaline mixing plays no role because these stars do not go through the RGB-bump on their short first ascent red giant branch, and thus thermohaline instability does not occur (see Sect. 3). This fact explains why our simulations do not reproduce the spread of $[C/N]$ ratio observed in clusters more massive than $2.2 M_\odot$ (see Fig.9), and younger than 0.5 Gyr (see Fig.10). As known

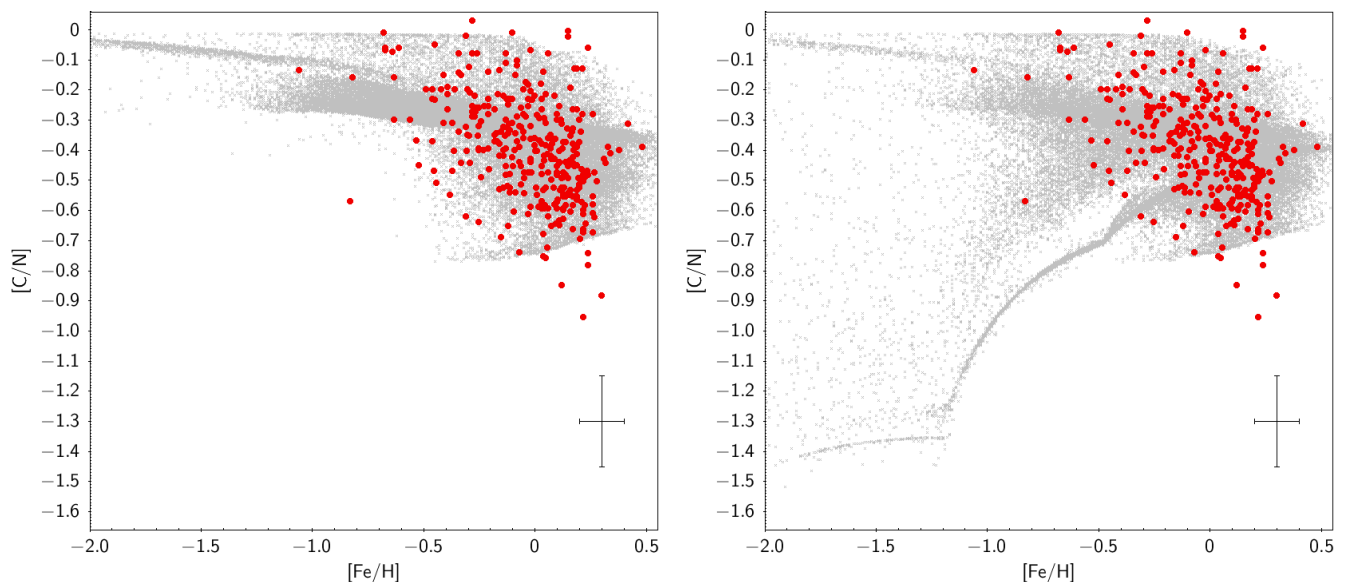

Fig. 6. $[C/N]$ as a function of $[Fe/H]$ for synthetic populations computed with the BGM including the effects of thermohaline instability (right panel) or not (left panel). $[C/N]$ ratio for our sample of UVES giant field stars are also shown (red dots).

Fig. 7. *Left and middle panels:* $[C/N]$ distributions for the same synthetic populations of Fig.6 including the effects of thermohaline instability (middle panel) or not (left panel). $[C/N]$ ratio for our sample of UVES giant field stars are also shown (red histogram). *Right panel:* $[C/N]$ distributions for a synthetic populations computed with the BGM for the globular cluster NGC104 including the effect of thermohaline instability (blue histogram) or not (black histogram). The observed $[C/N]$ ratio derived by GES survey is shown (red histogram).

for a long time (e.g. Meynet & Maeder 2002; Palacios et al. 2006; Charbonnel & Lagarde 2010), rotation-induced mixing has an impact on the internal chemical structure of main sequence stars, although its signatures are revealed only later at the beginning of the RGB. This results in a decrease of the surface abundances of C while N increases. We plan to focus on the effects of rotation on stellar ages and chemical properties in a separate forthcoming paper.

We note that using the twelfth data release of the APOGEE survey, Masseron & Gilmore (2015) showed that extra-mixing has occurred in thin disc stars, but indicated that thick disc stars do not show any evidence for a such extra-mixing process. They proposed that the thick disc stars could be formed with a different initial abundances than thin disc stars. We also note that our simulations reproduce very well observations in clusters having metallicity corresponding to the thick disc or halo population assuming the same initial abundances for all populations. However, our comparison is based on clusters members, and complementary to this study it is crucial to consider a larger sample of thick disc field stars such as those observed by APOGEE survey. In addition, chemical evolution model and population synthesis model should be combined to study the effects of different initial abundances for the different populations before to conclude.

4.3. $^{12}C/^{13}C$ in field stars and clusters

GES cannot derive the carbon isotopic ratio due to the wavelength regions observed with no good ^{13}CN features, thus in this part we use data from other studies to investigate the importance of $^{12}C/^{13}C$ to constrain extra-mixing on the red giant branch.

Figures 11 and 12 present the carbon isotopic ratio as a function of C/N and as function of stellar masses and ages, for synthetic populations computed with the BGM taking into account the effects of thermohaline mixing (grey dots) or not (green dots). The carbon isotopic ratio decreases abruptly when the thermohaline mixing develops in RGB stars as already shown by Charbonnel & Lagarde (2010). This is in agreement with the observed abundance ratios found in field stars and open clusters, shown with symbols in the figures (Mikolaitis et al. 2012; Drazdauskas et al. 2016; Tautvaišienė et al. 2016). Whereas the range of $[C/N]$ values agree with both models in the observed range, the low values of $^{12}C/^{13}C$ cannot be reproduced without extra-mixing process. As discussed below in the $[C/N]$ case, thermohaline mixing explains very well the low-mass (and older) giants stars, contrary to higher mass stars. This emphasizes out that $^{12}C/^{13}C$ is a more powerful parameter to constrain extra-mixing on the RGB than $[C/N]$ ratio, including for solar metallicity stars.

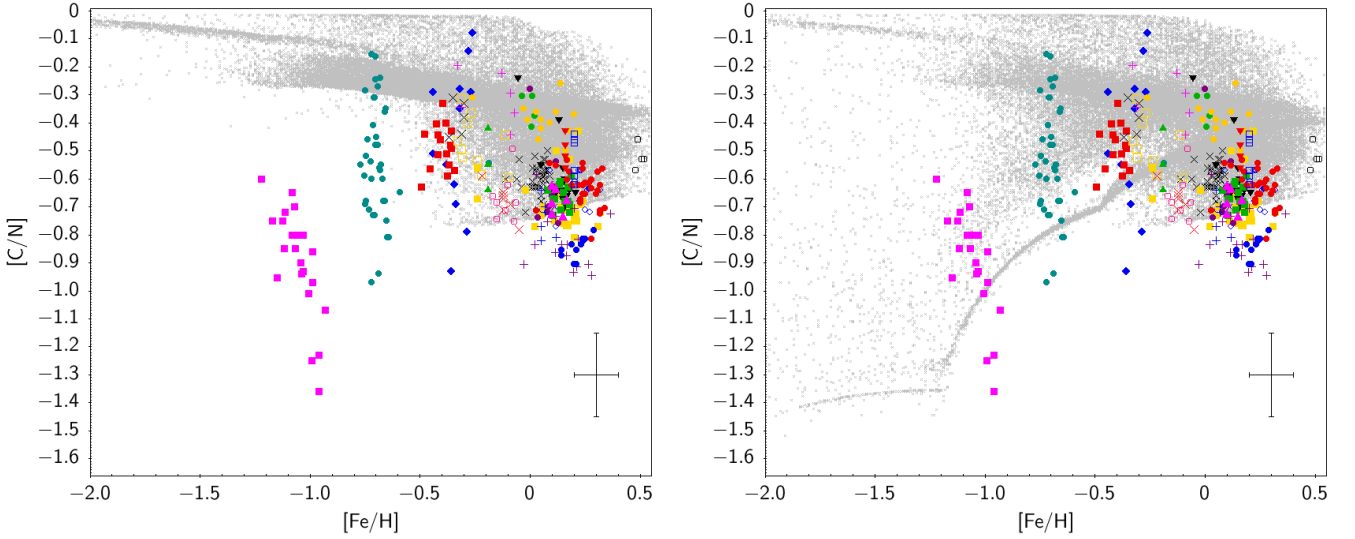

Fig. 8. $[C/N]$ as a function of $[Fe/H]$ for synthetic populations computed with the BGM including the effects of thermohaline instability (right panel) or not (left panel). $[C/N]$ ratio for our sample of UVES giant stars members of open and globular clusters are also shown (each color-symbol represents a cluster, see table 1). A typical error bar is indicated.

Fig. 9. $[C/N]$ as a function of stellar mass for synthetic populations computed with the BGM including the effects of thermohaline instability (right panel) or not (left panel). $[C/N]$ ratio for our sample of UVES giant stars members of open and globular clusters are also shown (each color-symbol represents a cluster, see table 1). A typical error bar is indicated.

5. Conclusions

In this paper, we present the first comparison between synthetic populations computed with the Besançon Galaxy model and the C and N abundances derived by the Gaia-ESO survey in field stars as well as in different (globular and open) clusters. We conclude from this work that it is crucial to take into account thermohaline mixing to understand the C and N observed at the surface of low-mass stars, and in the determination of the stellar mass and age from their chemical properties (Martig et al. 2015; Ness et al. 2016).

We compared data from the Gaia-ESO survey with predictions computed using the Besançon Galaxy model in which we included stellar evolution models taking (or not) into account the effects of thermohaline instability (Paper I). Up to now, this mixing is the only physical process proposed in the literature to explain the photospheric composition of evolved red-giant stars.

We focus in the first part of this paper on field stars because of their wide-coverage properties (e.g. mass, metallicity, and ages) to deduce an "observational" trend between $[C/N]$ ratio and stellar mass, metallicity, or ages. Due to the lack of C and N determinations in field stars at low metallicity, we can not investigate further the observational constraints in the metallicity domain where thermohaline instability is more efficient. Nevertheless, theoretical distribution of $[C/N]$ predicted by the BGM including the effects of thermohaline instability is in better agreement than the standard one at metallicity close to solar.

We also investigate the $[C/N]$ ratio derived in giants members of open and globular clusters by the Gaia-ESO survey and literature. This comparison shows a very good agreement with stellar evolution models including thermohaline mixing over the whole scrutinized metallicity range, allowing to explain the $[C/N]$ ratio observed in lower-mass and older giant stars. This

Fig. 10. $[C/N]$ as a function of stellar ages for synthetic populations computed with the BGM including the effects of thermohaline instability (right panel) or not (left panel). $[C/N]$ ratio for our sample of UVES giant stars members of open and globular clusters are also shown (each color-symbol represents a cluster, see table 1)

Table 1. References for the chemical properties of globular and open clusters used in the comparison with model predictions. For GES clusters, the approximate turn-off masses were evaluated using the theoretical PARSEC isochrones (Bressan et al. 2012) with the corresponding ages and metallicities. For globular clusters see in the text ; and for clusters already published we use the turnoff mass and age indicated in the corresponding article.

Fig. 11. $^{12}\text{C}/^{13}\text{C}$ as a function of $[\text{C}/\text{N}]$ for synthetic populations computed with the BGM including the effects of thermohaline instability (grey dots) or not (green dots) for upper-RGB and clump stars. A sample of clump field stars are represented by black dots on the right panel, and 9 clusters (Collinder 261, Melotte 66, NGC6253, NGC3960, NGC2324, NGC2477, NGC2506, IC4651, NGC6134) using different color and symbols (see table 1).

confirms that thermohaline instability is a crucial extra-mixing to understand the chemical properties of giant stars. The next step is to use a larger sample of field stars to strengthen this encouraging results.

On the other hand, we show that the observed behavior of carbon isotopic ratio with the stellar ages is definitively reproduced by models including the effect of thermohaline mixing. This confirms the importance, amongst others, of extra-mixing to deduce the stellar ages from the chemical properties of giant stars.

Additionally and independently of spectroscopy, asteroseismology paves the way to a better understanding of stellar interiors, providing valuable and independent constraints on current stellar evolution models as well as on the physics of different transport processes. The space missions CoRoT (Baglin et al. 2006), *Kepler* and K2 (Borucki et al. 2010) observed a large number of giant stars in different regions in our Galaxy, allowing a unique opportunity to derive some fundamental properties (as stellar mass, radius, age and gravity, and evolutionary stage of giants) by observation of mixed modes in red giants (e.g. Chaplin & Miglio 2013). To obtain the most informations possible from the data sample, the asteroseismic properties must be combined with the observations of the surface chemical abundances and especially the surface $^{12}\text{C}/^{13}\text{C}$. Future studies of CoRoT inner-field stars (Valentini et al. in prep.) and K2 (campaign 3) giants already observed by GES, will provide complementary results for development of stellar evolution models.
